# QHack

## Quantum Coding Challenges

✓ Jump to code Collapse text 5. Hi, Hydrogen! 0 points

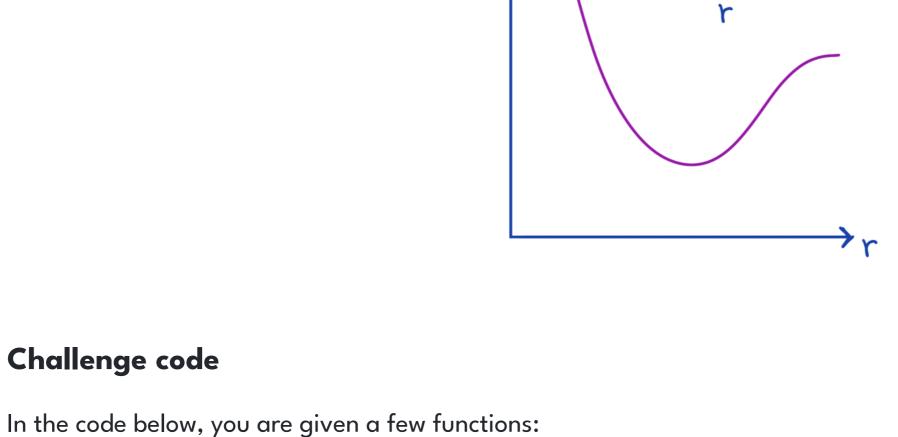

**CRISTIAN EMILIANO** 

Welcome to the QHack 2023 daily challenges! Every day for the next four days, you will receive two new challenges to complete. These challenges are worth no points — they are specifically designed to get your brain active and into the

right mindset for the competition. You will also learn about various aspects of PennyLane that are essential to quantum

computing, quantum machine learning, and quantum chemistry. Have fun! Tutorial #5 — Hi, Hydrogen! The Variational Quantum Eigensolver (VQE) algorithm has been touted as a game-changing near-term quantum algorithm. In particular, VQE is able to efficiently simulate low-energy properties of small molecules. In this challenge,

### you will calculate the energy of the hydrogen molecule for various molecular charges and bond length combinations.

• hydrogen\_hamiltonian: This function will return the qubit Hamiltonian of the hydrogen molecule, H2, given the

#### we'll spice it up with a non-zero charge!

Challenge code

• num\_electrons: In subsequent functions, we'll need the total number of electrons in the hydrogen molecule we're

this later, so you must complete this function.

looking at. With a charge of 0, H<sub>2</sub> usually has just 2 electrons, one per hydrogen atom. Given the charge, how many electrons should H<sub>2</sub> have? You must complete this function. • hf: The "HF" stands for Hartree–Fock. This function's purpose is calculate the HF approximation — treat every electron as independent, electrons move under a Coulomb potential from the positively charged nuclei, and there's

coordinates of both hydrogen atoms and the net molecular charge. You'll usually find H2 with a charge of 0, but here

• run\_VQE: This function takes the coordinates, charge, generates the HF state, defines a cost function and minimizes it. **You must complete this function** by: • defining the gates within the cost function, using the qml.AllSinglesDoubles template with singles and doubles arguments defined below; and

a mean field from the other electrons — for the ground state of the hydrogen molecule we're interested in. We'll use

- Here are some helpful resources: • Building molecular Hamiltonians
  - A brief overview of VQE • Variational Quantum Eigensolver

• returning what we want to minimize, namely the expectation value of the hydrogen Hamiltonian!

• Quantum Chemistry documentation

#### Input

Args:

Output

Good luck!

Copy all

print("Correct!")

weights = opt.step(cost, weights)

Code

- As input to this problem, you are given:
  - coordinates (list(float)): the x, y, and z coordinates of each hydrogen atom • charge (int): the charge of the hydrogen molecule. It could be positive, negative, or zero!
- If your solution matches the correct one within the given tolerance specified in <code>check</code> (in this case it's a <code>le-3</code> relative error tolerance), the output will be "Correct!" Otherwise, you will receive a "Wrong answer" prompt.

This code must output the ground state energy (float) of the hydrogen molecule in question.

import pennylane.numpy as np def hydrogen\_hamiltonian(coordinates, charge):

coordinates (list(float)): Cartesian coordinates of each hydrogen molecule.

? Help
